## Abstract

We provide an overview and synthesis of recent work on models of monopolistic competition with heterogeneous firms in international trade, paying particular attention to competition effects, pass-through, selection effects, and linking distributions of firm characteristics and outcomes. A recurring theme is that CES preferences are extremely convenient for deriving analytic results, but also extremely restrictive in their theoretical and empirical implications. We introduce the class of “constant-response demand functions” to describe some related families of demand functions that provide a unifying principle for much recent work that explores alternatives to CES demands.

# 1 Introduction

In this paper we aim to provide an overview of recent research in international trade, from the perspective of the theory of industrial organization (henceforth IO). There are two aspects to this perspective, mirroring the two different interpretations of our title. On the one hand, we are interested in “IO for *Exports*”: what is the structure of export markets?; how does that structure affect which firms export?; does trade fosters competition?; and a host of other similar questions. On the other hand, we want to think about “IO for *Export*”: which IO models are used in trade? As is well-known, the answer to the latter question is not any of the many varieties of oligopoly used in IO itself, but rather the monopolistically competitive model of Chamberlin (1933), as formalized by Dixit and Stiglitz (1977); especially with Constant-Elasticity-of-Substitution (CES) preferences, introduced as a special case by Dixit and Stiglitz (1977), brought to center stage by Dixit and Norman (1980) and Krugman (1980) among many others, and extended to firm heterogeneity by Melitz (2003). Ironically, though monopolistic competition originated in IO, it is used relatively rarely there, so it could be described as “IO for export *only*.”<sup>1</sup>

While monopolistic competition is by far the dominant paradigm in international trade, it is by no means the only approach. First there is a large literature on “strategic” trade policy, dating from the 1980s, that uses off-the-shelf IO models of oligopoly to address standard issues of trade policy, mostly at the level of a single industry.<sup>2</sup> Second, there have been some attempts to explore the implications of oligopoly in general equilibrium for trade questions, both of the traditional kind such as trade patterns, gains from trade and pricing-to-market,<sup>3</sup> and also with applications to topics such as cross-border mergers and

---

<sup>1</sup>See Neary (2003b) for further discussion. Of course, studies of monopolistic competition, in both CES and non-CES cases, are not completely absent from IO. Examples include advanced textbook treatments by Anderson et al. (1992) and Vives (1999), as well as studies of existence by Pascoa (1993) and Pascoa (1997), and of optimality by Kuhn and Vives (1999).

<sup>2</sup>See Brander (1995) for an overview, and Mrázová (2011) and Mrázová et al. (2013) for applications to trade agreements.

<sup>3</sup>See, for example, Neary (2003a), Atkeson and Burstein (2008), Neary (2016), Gaubert and Itskhoki (2018), and Nocke and Schutz (2018).

multi-product exporters.<sup>4</sup> Finally, there is a small literature on the theory of superstar firms that compete oligopolistically, while coexisting with a monopolistically competitive fringe.<sup>5</sup>

However, there are good reasons why the monopolistically competitive paradigm has remained dominant in trade. The availability of large data sets on exporting firms, and the desire to allow for entry and exit and to take account of general-equilibrium feedbacks to and from factor markets, make bespoke modelling of individual sectors infeasible, and a “one-size-fits-all” approach to the choice of market structure very convenient.

Two general themes emerge from our analysis, one old, one new. First, the widespread assumption of CES preferences, implying demand functions that are log-linear in price, is extremely convenient for deriving analytic results, but also extremely restrictive in its theoretical and empirical implications. Second, we introduce the class of “constant-response demand functions” to describe some related families of parametric demand functions that imply a constant absolute or relative response of some firm-level variable to an exogenous change in marginal cost. As we shall see, this class of demands, all of which nest the CES case, provides a unifying principle for much recent work, including our own, that explores alternatives to CES demands.<sup>6</sup>

The plan of the paper is as follows. Section 2 introduces the basic underlying model and an approach to comparing different demand functions that we use throughout. It also discusses recent evidence that questions a key implication of CES preferences. Each of the four subsequent sections considers a substantive question, and asks, which demand functions arise naturally in trying to answer it? As we show, each question can be formulated in terms of a constant response of a target function to a change in costs, and so we are led to seeking demand functions that are consistent with such a constant response. Section 3 considers the central topic of competition effects, and shows that the CES demand function

---

<sup>4</sup>See, for example, Neary (2007), Eckel and Neary (2010) and Eckel et al. (2015).

<sup>5</sup>See, for example, Neary (2010), Shimomura and Thisse (2012), Parenti (2018), and Cabral (2018).

<sup>6</sup>For other approaches to going “beyond CES,” see Zhelobodko et al. (2012), Bertoletti and Epifani (2014), Parenti et al. (2017), Dhingra and Morrow (2019), and Matsuyama and Ushchev (2017). For the most part, these papers consider non-parametric families of demand functions, whereas in this paper we focus on families with explicit functional forms.

is a key benchmark in categorizing them, both at the firm level in the cross-section and in general equilibrium when the economy responds to exogenous shocks. Section 4 considers the issue of how cost changes are passed through to goods prices, and introduces the Bulow-Pfleiderer (B-P) and Constant-Proportional-Pass-Through (CPPT) demand functions that correspond to constant rates of absolute and proportional pass-through respectively. Section 5 turns to consider the central topic of selection effects, and introduces the Constant-Elasticity-of-Marginal-Revenue (CEMR) demand functions that provide a natural reference point for understanding them. Section 6 explores the relationship between the distribution of firm productivity, on the one hand, and the distributions of the level and growth rate of sales, on the other; and it introduces the Constant-Revenue-Elasticity-of-Marginal-Revenue (CREMR) demand functions that arise naturally in this context. Finally, Section 7 provides an overview of the constant-response demand functions introduced in earlier sections, and introduces a general demand function that nests three of them. Section 8 concludes. Proofs and further details can be found in our other papers: Mrázová and Neary (2017) for Sections 2, 3 and 4, Mrázová and Neary (2019) for Section 5, and Mrázová et al. (2015) for Section 6.

## 2 Preliminaries

### 2.1 A Core Model

We begin by presenting a simple core model of a monopoly firm. This serves to introduce the notation and setting that we will use throughout the remainder of the paper.

Consider a monopoly firm facing an inverse demand function  $p(x)$ , giving price as a strictly decreasing function of firm output  $x$ . This is consistent with monopolistic competition where the firm takes the “perceived” demand function as given. In general equilibrium, the demand function has extra arguments: we will see examples of that later. As for technology, we adopt the simplest specification popularized by Dixit and Stiglitz (1977): all firms

incur a fixed cost  $f$ , often assumed to be constant across firms, and a constant marginal cost of production  $c$ .<sup>7</sup> Profit maximization therefore implies simple first- and second-order conditions:

$$p + xp' = c \quad \text{and} \quad 2p' + xp'' < 0 \tag{1}$$

In words, marginal revenue must equal marginal cost, and marginal revenue must be declining in output at the optimum. It will prove convenient to write these conditions in terms of two key demand parameters:

$$\varepsilon(x) \equiv -\frac{p(x)}{xp'(x)} > 0 \quad \text{and} \quad \rho(x) \equiv -\frac{xp''(x)}{p'(x)} \tag{2}$$

Here  $\varepsilon(x)$  is the demand elasticity and  $\rho(x)$  the convexity of demand; these are unit-free measures of the slope and curvature of the demand function, respectively. Reexpressing the first- and second-order conditions in (1) in terms of these parameters yields, first, a simple expression linking the price-cost margin or markup,  $p/c$ , to the elasticity of demand, and, second, a restriction that convexity must be less than two:

$$\frac{p}{c} = \frac{\varepsilon}{\varepsilon - 1} \quad \text{and} \quad \rho < 2 \tag{3}$$

## 2.2 Demand Functions and Demand Manifolds

Throughout the paper, we will see many different parametric forms of demand function, and it is desirable to have some way of comparing them. As is foreshadowed in the previous section, for many questions of interest only the elasticity and convexity of demand matter.

Hence it makes sense, following Mrázová and Neary (2017), to illustrate different demand

---

<sup>7</sup>Dixit and Stiglitz should not be held responsible for the widespread use of CES preferences: they presented them only as an example, albeit with the unique implication of constrained efficiency (see their Section I), and each of them is on record as expressing reservations about them: see Dixit (2004) and Stiglitz (2004). However, they deserve credit for popularizing, and perhaps making respectable, the very simple  $\{f, c\}$  technology. Ironically, this is another example of IO for export only: it is now ubiquitous in trade, whereas more complicated cost functions are often used in the IO literature.

Figure 1: The Admissible Region in Convexity-Elasticity Space

functions in the space of these two parameters, as in Figure 1. The shaded area represents the admissible region implied by the restrictions in equation (3): at a profit-maximising equilibrium, a monopoly firm must be at a point on its demand function where the elasticity is greater than one, and the convexity is less than two.<sup>8</sup>

The space illustrated in Figure 1 may seem unfamiliar at first, so it is desirable to have some landmarks. One such is the linear demand curve: it implies that convexity is zero, and so it is represented by the vertical line at  $\rho = 0$  in Figure 2. It turns out that a more important benchmark is that of CES demands:

$$p(x) = \beta x^{-1/\sigma} \quad \Rightarrow \quad \varepsilon = \sigma \quad \text{and} \quad \rho = \frac{\sigma + 1}{\sigma} \quad (4)$$

This is the only exception to the general rule that both  $\varepsilon$  and  $\rho$  vary with sales: in the CES case their values are uniquely determined by the elasticity of substitution  $\sigma$ . Eliminating  $\sigma$  from those expressions gives the relationship between elasticity and convexity implied by

<sup>8</sup>Of course, the admissible values of  $\varepsilon$  are unbounded above and those of  $\rho$  are unbounded below. The range of values illustrated in the figures is broadly in line with the available empirical evidence: see for example Mrázová and Neary (2017), footnote 8 and Section IV.A.

CES demands:

$$\varepsilon = \frac{1}{\rho - 1} \tag{5}$$

This relationship is illustrated by the curve labelled “CES” in Figure 2; it ranges from an asymptotically infinite value of  $\varepsilon$  as  $\rho$  approaches one to a value of  $\varepsilon$  equal to one when  $\rho$  equals two. Each point on this curve represents a particular CES demand function corresponding to a particular value of  $\sigma$ ; for example, the point  $\{\rho = 2, \varepsilon = 1\}$ , just on the boundary of the admissible region, corresponds to the Cobb-Douglas special case.

Figure 2: Demand Manifolds for Some Common Demand Functions

The linear and CES demand functions are not the only ones that can be illustrated in  $(\rho, \varepsilon)$ -space. As shown in Mrázová and Neary (2017), any demand function can be illustrated in this space by a smooth curve, which they call the “demand manifold” corresponding to the demand function. (The only exception is CES demands, where as we have seen the manifold is a single point.) Figure 2 illustrates the manifolds for three other widely-used demand functions: the negative exponential or CARA (“constant absolute risk-aversion”) system, the Stone-Geary LES (“linear expenditure system”), and the translog (which from a firm’s perspective is observationally equivalent to the “Almost Ideal” system of Deaton and

Muellbauer (1980)).<sup>9</sup> (Explicit expressions are in Appendix B.)

There are a number of advantages to considering demand functions through the lens of their manifolds. First, different demand functions can be directly compared with each other. For example, Figure 2 shows that, despite their very different origins and system-wide properties, all three of CARA, LES and translog demands have properties at the firm level that are midway between those of linear and CES demands. In particular, for a given demand elasticity they are all less convex than CES demands, though they are more so than linear demands.

Second, demand manifolds make it possible to relate assumptions about demand directly to comparative statics properties: we will see examples of this later. Finally, though the location of a demand function in  $(x, p)$ -space is affected by the values of all its parameters, the location of its manifold in  $(\rho, \varepsilon)$ -space is often unaffected by, or invariant to, the values of these parameters. Mrázová and Neary (2017) call this property “manifold invariance”, and provide necessary and sufficient conditions for it to hold. Not all demand functions exhibit this property with respect to some of their parameters, far less to all of them. The latter is true of the CES for example: the CES point-manifold is invariant with respect to changes in the level parameter  $\beta$  but not to changes in the elasticity of substitution  $\sigma$ . However, many demand functions have manifolds that are invariant to some of their parameters, and some (including all those other than the CES in Figure 2) have manifolds that are invariant to all of them. This makes it much easier to think about the implications of different demand assumptions using the demand manifold than the demand function itself, since the latter is never invariant to any parameter changes.

---

<sup>9</sup>The non-CES demand functions whose manifolds are shown in Figure 2 have been explored in monopolistic competition with heterogeneous firms by a number of authors. Melitz and Ottaviano (2008) consider linear demands; Behrens and Murata (2007) CARA demands; Simonovska (2015) the LES; and Feenstra and Weinstein (2017) the translog.

## 2.3 Evidence on Variable Markups

Of the demand functions in Figure 2, the CES is by far the most widely-used in international trade. However, it makes implausible empirical predictions, in particular that markups are always the same, and depend only on the preference parameter  $\sigma$ :  $p/c = \sigma/(\sigma - 1)$ . International trade economists have always been uneasy with these implications, even more so in recent years as persuasive evidence against them has become available.

Figure 3: Empirical Evidence on Markup Distributions  
Sources: De Loecker et al. (2016) and Lamorgese et al. (2014)

A key reference is De Loecker et al. (2016), who calculate markups for a sample of Indian firms without making prior assumptions about market structure or the form of demand. Figure 3(a) from their paper shows that the distribution of markups is very far from being concentrated at a single value. A possible explanation is that such markup heterogeneity arises from aggregation across sectors with different elasticities of substitution. However, Figure 3(b) from Lamorgese et al. (2014), who use data on Chilean firms, show that heterogeneity persists when the data are disaggregated by sector. This evidence clearly rejects the hypothesis of monopolistic competition with CES preferences. One way to allow for variable markups is to retain CES preferences but assume an oligopolistic market structure as in Atkeson and Burstein (2008). In this paper we explore instead how non-CES preferences in

monopolistic competition have been used to throw light on a variety of substantive questions in international trade.

### 3 Competition Effects

The first substantive topic we wish to discuss is that of competition effects. The term “competition effects” can be used in two different senses in this context.<sup>10</sup> On the one hand, it can refer to the fact that markups vary across firms in the cross-section. On the other hand, it can refer to the fact that any exogenous shock to industry equilibrium affects firms indirectly by changing the competitive environment in which they operate, in addition to its direct effect on individual firms. As we will see, CES demands are a key reference point for competition effects in both senses: with CES demands, competition effects do not arise in the cross section, while, in response to a change in market size, the direct effect of the shock on firm profits is exactly offset by the induced general-equilibrium competition effect.

#### 3.1 Competition Effects in the Cross Section

Consider first competition effects in the cross-section sense. To understand how they operate, consider Figure 4, which repeats the CES locus, henceforward labelled “SC”, from Figure 2. This locus divides the admissible region in  $(\rho, \varepsilon)$ -space into two sub-regions that imply very different comparative statics properties. Crucially, they differ in how the elasticity of demand varies with firm output:

$$\varepsilon_x = \frac{\varepsilon}{x} \left( \rho - \frac{\varepsilon + 1}{\varepsilon} \right) \quad (6)$$

This is negative when  $\rho$  is less than its CES value of  $\frac{\sigma+1}{\sigma}$ . (Recall equation (4).) Mrázová and Neary (2019) call demand functions with this property “subconvex”, and in Figure 4

---

<sup>10</sup>See, for example, Krugman (1979), Melitz (2003), Melitz and Ottaviano (2008) and Zhelobodko et al. (2012).

Figure 4: The Sub- and Super-Convex Regions

they are represented by the set of points in the region to the left of the SC locus.<sup>11</sup> When the demand curve exhibits this property, larger firms face a lower elasticity of demand and hence have higher markups in the cross section, and all firms enjoy higher profit margins as they move down their demand curves over time. (The arrows in the figure indicate how elasticity changes as firm output rises.) In the converse case, of superconvexity, all these properties are reversed. However, subconvexity is theoretically more plausible, both on introspective grounds (see Marshall (1920));<sup>12</sup> and also in that it leads to more plausible predictions (see Dixit and Stiglitz (1977) and Krugman (1979)). Hence we can conclude that CES demands rule out competition effects, and subconvex demands are necessary and

<sup>11</sup>Formally, subconvexity is a local property, and is defined as  $\log p(x)$  being concave in  $\log x$  at a point. Mrázová and Neary (2019) show that this property is equivalent to those stated in the text. It is possible for the same demand function, with given parameters, to be subconvex for some levels of output and superconvex for others. (For an example, see Mrázová and Neary (2017), Online Appendix B10.) However, this property is rare, at least as far as most widely-used demand functions is concerned. Moreover, as the argument in the text shows, the manifold implied by such a demand function must be horizontal at the point where it crosses the SC locus, since it is falling in output to the left and rising to the right: see the horizontal arrows in Figure 4.

<sup>12</sup>In Chapter 3 of Book 4 of his *Principles*, Marshall introduced his “law of demand” – in modern parlance, demand curves slope downwards – while in Chapter 4 he introduced what he called “the general law of variation of the elasticity of demand”: “The elasticity of demand is great for high prices, and great, or at least considerable, for medium prices; but it declines as the price falls; and gradually fades away if the fall goes so far that satiety level is reached.” Hence the property is sometimes called “Marshall’s Second Law of Demand.”

sufficient for monopolistic competition to exhibit the empirically plausible case where larger firms have higher markups.

### 3.2 Competition Effects of a Globalization Shock

Consider next the second sense of competition effect: the general-equilibrium effect of an exogenous shock on the competitive environment faced by all firms. An important and interesting example of this is the effects of globalization, in the sense of an increase in the size of the global economy.

To see how competition effects arise following a globalization shock, we need to go beyond the “firm’s eye view” we have adopted so far, and consider the determination of industry equilibrium.<sup>13</sup> Also, since we want to allow for firms to sell in many markets, we distinguish for the first time between their total output  $y$  and the amount they sell to an individual consumer  $x$ . Following Krugman (1979), we take the simplest setting, where all consumers are identical, there are  $L$  of them in each country, and the world consists of  $k$  identical countries, so  $y = kLx$ . In addition, though this is not needed for all our results, it is convenient to assume that preferences are additively separable, so the demand function for a typical good is given implicitly by the consumer’s first-order condition  $u'(x) = \lambda p$ , where  $\lambda$  is the marginal utility of income.<sup>14</sup> With these assumptions, we can write the ex-post profits of a typical firm as follows:

$$\pi(\underset{-}{c}, \underset{-}{\lambda}, \underset{+}{k}) \equiv \max_y \left( p(y, \lambda, k) - c \right) y \quad \text{where} \quad p(y, \lambda, k) = \lambda^{-1} u'(y/kL) \quad (7)$$

In previous sections we considered the demand function from a firm’s perspective only. Now

---

<sup>13</sup>This section is based on Mrázová and Neary (2017), Section III.B. See also Zhelobodko et al. (2012), Bertolotti and Epifani (2014), Mrázová and Neary (2014), and Bache and Laugesen (2015).

<sup>14</sup>Writing the demand for each good as  $p(y, \lambda, k)$ , a function of its own quantity consumed, a single demand-side aggregate  $\lambda$ , and the exogenous shock  $k$ , corresponds to generalized additive separability, introduced by Pollak (1972). Our results, up to and including equation (10) below, hold in this case, though their interpretation is simpler when, as in (11), we specialize to additive separability, which implies that  $\lambda$  equals the marginal utility of income.

we want to solve explicitly for the industry equilibrium, so we need to consider demand determinants additional to their sales. In (7) these are  $k$ , the exogenous globalization shock, equal to the number of identical countries in the world, and  $\lambda$ , the marginal utility of income under additive separability, which plays the role of the level of competition in the industry. This is exogenous to each firm, but is determined endogenously in industry equilibrium by the free-entry condition, which requires that an entrant has zero expected value. Denoting by  $\bar{v}(\lambda, k)$  the expected value of firm profits, this can be written as follows:

$$\bar{v}(\lambda, k) \equiv \int_{\underline{c}}^{\bar{c}} v(c, \lambda, k) g(c) dc = f_e, \quad v(c, \lambda, k) \equiv \max(0, \pi(c, \lambda, k) - f) \quad (8)$$

Here  $g(c)$  is the distribution of firm marginal costs. Prospective firms know this but do not know their own marginal cost ex ante; to find that out they have to pay a sunk entry cost  $f_e$  in order to make a draw from the distribution. This sunk cost must therefore equal the expected return to sampling from  $g(c)$ , which with rational expectations and risk neutrality equals  $\bar{v}(\lambda, k)$ .

We can solve for the effects of globalization on every firm's profits by totally differentiating (7):

$$\frac{d \log \pi(c, \lambda, k)}{d \log k} = \underbrace{\frac{\partial \log \pi(c, \lambda, k)}{\partial \log k}}_{(M)} + \underbrace{\frac{\partial \log \pi(c, \lambda, k)}{\partial \log \lambda} \frac{d \log \lambda}{d \log k}}_{(C)} \quad (9)$$

where the change in the level of competition is determined in turn by (8):

$$\frac{d \log \lambda}{d \log k} = - \frac{\partial \log \bar{v}(\lambda, k)}{\partial \log k} \bigg/ \frac{\partial \log \bar{v}(\lambda, k)}{\partial \log \lambda} \quad (10)$$

Equation (9) shows that globalization is a double-edged sword from the perspective of firms. On the one hand it has a market-size effect, given by (M), which tends to *raise* each firm's profits. On the other hand it has a competition effect, given by (C): because *all* firms' profits rise at the initial level of competition, the latter must increase to ensure that the expected value of a firm remains equal to the fixed cost of entry; this in turn tends to *reduce* each firm's

profits. The net outcome is indeterminate in general. However, with additive separability, equation (9) takes a particularly simple form:

$$\frac{d \log \pi(c, \lambda, k)}{d \log k} = \underbrace{1}_{(M)} - \underbrace{\frac{\varepsilon(c, \lambda, k)}{\bar{\varepsilon}(\lambda, k)}}_{(C)} \quad (11)$$

Now the market expansion effect is just one: other things equal, a 1% increase in market size leads to a 1% increase in the profits of each firm. As for the competition effect, it depends on the ratio of the demand elasticity the firm faces to  $\bar{\varepsilon}$ , which is defined as follows:

$$\bar{\varepsilon}(\lambda, k) \equiv \int_{\underline{c}}^{\bar{c}} \frac{v(c, \lambda, k)}{\bar{v}(\lambda, k)} \varepsilon(c, \lambda, k) g(c) dc \quad (12)$$

Here  $\bar{\varepsilon}$ , which we can interpret as the elasticity faced by the average firm. Higher competition reduces an individual firm's profits by  $\varepsilon$ , while it reduces the average value of a firm by  $\bar{\varepsilon}$ . Recalling from (6) that elasticity falls with output if and only if demand is subconvex, we see from (11) that the ambiguity in the general case is resolved in a very simple way when preferences are additively separable: globalization raises profits of larger firms and reduces those of smaller firms if and only if demands are subconvex.

Figure 5: The Matthew Effect of Globalization

Figure 5 illustrates these effects in the case of subconvexity. The curve labelled  $\Pi_0$  shows the initial profit profile across firms of different productivity, while that labelled  $\Pi_1$  shows the profit profile after globalization, assuming that demand is strictly subconvex. The productivity level denoted  $T_0$  is that corresponding to threshold firms in the initial equilibrium: they make zero profits and so are indifferent between producing or not; while that denoted  $A$  corresponds to the average firm that faces the demand elasticity  $\bar{\varepsilon}$ . As can be seen, in line with equation (12), the direct, market-expansion, effect dominates for firms of above-average size,  $\varepsilon < \bar{\varepsilon}$ , so they expand; the indirect, competition, effect dominates for firms below average size,  $\varepsilon > \bar{\varepsilon}$ , so they contract; and threshold firms cease to be profitable and exit. One way of expressing this outcome is that, with subconvex demand, globalization has a clear “Matthew Effect” on profits, in the sense that “To those who have, more shall be given.”<sup>15</sup> An important consequence of these responses is that the average productivity of active exporters rises. Finally, recall that all these effects are reversed with superconvex demands. Moreover, the CES case is very special: the direct market-size effect and the indirect competition effect of globalization exactly offset each other, so the profit profile in Figure 5 is unaffected.

## 4 Pass-Through

The next substantive question we address is that of pass-through from costs to prices. The topic is of interest in itself but also as an illustration of how differently the same problem is addressed in IO and in international economics.

### 4.1 Pass-Through in Industrial Organization

The archetypical pass-through question posed in industrial organization is both simple and important: if marginal cost rises by a euro, by how much will a profit-maximizing firm

---

<sup>15</sup>In Mrázová and Neary (2017) we show that, subject to a technical qualification, the same effects arise for the profiles of outputs and prices: firms with above-average productivity sell more at lower prices.

raise its price; i.e., how large is  $dp/dc$ ? The answer is easy to calculate from the first-order condition in (1):<sup>16</sup>

$$p + xp' = c \quad \Rightarrow \quad \frac{dp}{dc} = \frac{1}{2 - \rho} \quad (13)$$

Thus a shock to costs is passed through to prices by more the more convex is the demand function. Moreover, the threshold for full, or “euro-for-euro”, pass-through is that the degree of convexity is exactly one:

$$\frac{dp}{dc} - 1 = \frac{\rho - 1}{2 - \rho} = 0 \quad (14)$$

Demand functions implying constant pass-through are members of the Bulow-Pfleiderer family, due to Bulow and Pfleiderer (1983):<sup>17</sup>

$$p(x) = \beta \left( x^{\frac{1-\kappa}{\kappa}} + \gamma \right), \quad \beta \frac{1-\kappa}{\kappa} < 0 \quad (15)$$

This implies a constant pass-through coefficient equal to  $\kappa$ :  $dp/dc = \kappa$ . Special cases of this include linear demand, with convexity  $\rho$  equal to zero and a constant pass-through of  $\kappa = 1/2$ ; and log-linear direct demand,  $p(x) = \beta'(\log x + \gamma')$ , corresponding to a limiting case of (15) with exactly one-for-one pass-through,  $\kappa = 1$ .<sup>18</sup> The latter demand function has convexity  $\rho$  equal to one, and so is the demand function implied by the condition in (14) holding globally. In general, values of  $\kappa > 1$  and  $\rho > 1$  correspond to log-convex direct demand, and values of  $\kappa < 1$  and  $\rho < 1$  to log-concave demand.

---

<sup>16</sup>This condition can be found in Cournot (1838), p. 79, which even allows for variable marginal cost. See also Bontems (2019).

<sup>17</sup>This demand function is more familiar when written, in the notation of Bulow and Pfleiderer, as  $p = \alpha - \beta x^\delta$ , when  $\delta \neq 0$ , and  $p = \alpha - \beta \log x$ . We write it differently to facilitate comparison with other demand functions to be introduced later.

<sup>18</sup> The limit has  $\kappa \rightarrow 1$ ,  $\beta \rightarrow \infty$ , and  $\gamma \rightarrow -1$ . To see this, set  $\beta = \beta' \frac{\kappa}{1-\kappa}$  and  $\gamma = \gamma' \frac{1-\kappa}{\kappa} - 1$  and evaluate the limit when  $\kappa \rightarrow 1$ , using for example a limited expansion.

## 4.2 Pass-Through in International Economics

Pass-through is also widely studied in international economics, both pass-through from tariffs to domestic prices in international trade, and pass-through from exchange rates to domestic prices in international monetary economics. However, the approach is totally different from that in industrial organization: compare for example Gopinath and Itskhoki (2010) with Weyl and Fabinger (2013), both important papers that refer to large literatures but have only a single reference in common.<sup>19</sup> It is not merely the answers that differ between the two fields, but the questions too. In IO the focus is on absolute or euro-for-euro pass-through as we have seen, whereas in international economics the question posed relates to proportional pass-through: how large is  $d \log p / d \log c$ ? Both approaches make perfect sense in their respective contexts: IO scholars are typically analysing the effects of a cost or tax change on a single industry, whereas in international economics the focus is on a change in policy or exchange rates at the economy-wide level. The first question is a partial-equilibrium one, so it is natural to work with absolute changes, whereas the second is a general-equilibrium one, mandating a focus on relative prices and proportional changes. However, it is important to understand the differences between the two.

Once again, the expression for proportional pass-through can be derived from the first-order condition (1):

$$\frac{d \log p}{d \log c} = \frac{\varepsilon - 1}{\varepsilon} \frac{1}{2 - \rho} \quad (16)$$

Unlike the corresponding term for absolute pass-through, (13), this depends on the elasticity of demand as well as its convexity. So, the threshold for full (100%) proportional pass-through is:

$$\frac{d \log p}{d \log c} - 1 = \frac{\varepsilon \rho - \varepsilon - 1}{2 - \rho} = 0 \quad (17)$$

This is equivalent to the demand function taking the CES form, as we have already seen that only in that case is the ratio  $p/c$  constant. (To show this explicitly, substitute for the

---

<sup>19</sup>The papers cite 41 and 86 references respectively, of which only Atkeson and Burstein (2008) is common to both.

convexity of CES demand from (4) into (17).) This suggests that pass-through will be more than 100% if and only if the demand function at the initial equilibrium is more convex than a CES demand function. We will return to this below.

We saw in the previous sub-section that an important benchmark is the Bulow-Pfleiderer demand family, which implies constant absolute pass-through. So it is natural to ask if there are demand functions other than the CES that imply constant proportional pass-through (CPPT):  $d \log p / d \log c = \kappa$ ,  $\kappa \neq 1$ . The answer to this question is the CPPT family, introduced in Mrázová and Neary (2017):<sup>20</sup>

$$p(x) = \frac{\beta}{x} \left( x^{\frac{\kappa-1}{\kappa}} + \gamma \right)^{\frac{\kappa}{\kappa-1}}, \quad \beta > 0, \quad \kappa \neq 1 \quad (18)$$

This family also has the property that it implies a constant proportional response of markups to marginal costs:  $d \log(p/c) / d \log c = \kappa - 1$ .

### 4.3 Comparing Absolute and Proportional Pass-Through

Casual inspection suggests that the CPPT demand functions in (18) are very different from the Bulow-Pfleiderer demands in equation (15). However, it is difficult to compare the two directly: they have different functional forms with three parameters each. Instead, we use the approach introduced in Section 2.2 of comparing the demand manifolds implied by the demand functions. This also allows us to compare visually the conditions that imply constant absolute and proportional pass-through.

By calculating the convexity of the Bulow-Pfleiderer demand function in equation (15), we can show that the implied demand manifold is given by:

$$\rho(\varepsilon) = 2 - \frac{1}{\kappa} \quad (19)$$

which is independent of  $\varepsilon$ . Similarly, by calculating both the elasticity and convexity of the

---

<sup>20</sup>The parameter  $\gamma$  must be strictly positive to ensure that the elasticity of demand exceeds one.

CPPT demand function in equation (18), the implied demand manifold is given by:

$$\rho(\varepsilon) = 2 - \frac{1}{\kappa} \frac{\varepsilon - 1}{\varepsilon} \quad (20)$$

These manifolds are illustrated for different values of  $\kappa$  in the two panels of Figure 6.

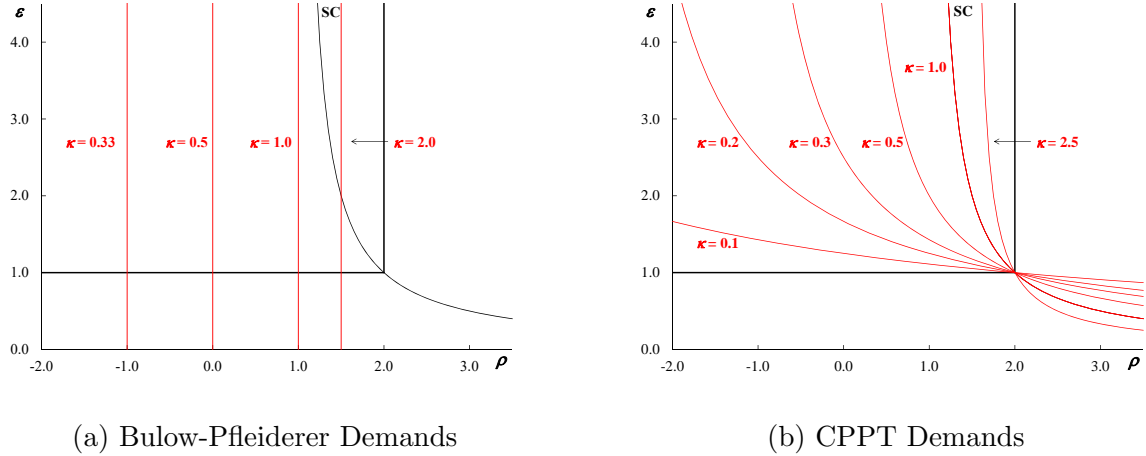

Figure 6: Constant Pass-Through Demand Manifolds

It is clear that the manifolds are much easier to compare than the corresponding demand functions. Whereas each demand function has three distinct parameters, each manifold is invariant with respect to two of these parameters, and depends only on the pass-through coefficient  $\kappa$ . The manifolds show clearly how demand adjusts as output rises (which in the subconvex region is equivalent to the elasticity falling). Bulow-Pfleiderer demands have constant convexity (given the one-to-one relationship between demand convexity and absolute pass-through from (13) and (19)), while CPPT demands become more convex as elasticity falls.

The demand manifolds in Figure 6 are not only the manifolds implied by the Bulow-Pfleiderer and CPPT demand functions, they are also contour lines corresponding to different values of  $\kappa$ , the degree of either absolute or proportional pass-through. As a result, they can be combined with the demand manifolds for any other demand functions to read off the

rates of pass-through implied by those demands. For example, recalling the CARA, LES and translog demand manifolds in Figure 2, we can see that all three imply a higher level of absolute pass-through for large firms; LES demands imply a constant rate of proportional pass-through for all firms, equal to 0.5, whereas CARA demands imply that the rate of proportional pass-through decreases with firm size, and translog demands imply that it increases.

## 5 Selection Effects

We turn next to one of the most distinctive and novel features of models with heterogeneous firms: their ability to predict which firms will select into which activities. Consider first the question of which firms will choose to export. Here the key prediction of the Melitz (2003) model is that more productive firms select into exporting. It turns out that this is an extremely robust result. It requires only that ex post profits  $\pi$  are decreasing in  $c$ , which must be true in all models of this kind. To see this, write the maximized value of operating profits as follows:

$$\pi(\tau, c) \equiv \max_x \tilde{\pi}(x, \tau, c), \quad \tilde{\pi}(x, \tau, c) = (p(x) - \tau c)x \quad (21)$$

where  $\tau$  is an iceberg trade cost:  $\tau$  units must be produced and shipped to the export market in order for one unit to arrive. For simplicity, assume that  $\pi(\tau, c)$  is continuous in  $\{\tau, c\}$ . Differentiating (21) and invoking the envelope theorem, we can see that operating profits are unambiguously decreasing in  $c$ :

$$\pi_c = \tilde{\pi}_c = -\tau x < 0 \quad (22)$$

This result is independent of the form of the demand function; in particular, it is not sensitive to whether demands are CES or not. Hence, ranking firms by their productivity, or inverse

marginal cost, unambiguously predicts their ranking by total profits,  $\Pi = \pi - f$ . So there must be a unique threshold level of productivity, with all firms more productive than the threshold choosing to export and all those less productive choosing not to.

Figure 7: Selection into Exports versus FDI

Consider next the case where each firm has the option of choosing to serve a market in two alternative ways, either by exporting (E) or by engaging in foreign direct investment (FDI). Firms therefore face a “proximity-concentration trade-off”: FDI entails operating a foreign plant and selling to foreign consumers without incurring the trade cost, so  $\tau = 1$ ; however, it foregoes the benefits of concentrating production at home, since it incurs a fixed cost  $f_F$  that is higher than the fixed cost of exporting  $f_E$ :

$$\Pi(\tau, c) = \max \begin{cases} \Pi^F(c) = \pi(1, c) - f_F \\ \Pi^E(\tau, c) = \pi(\tau, c) - f_E \end{cases} \quad (23)$$

The outcome under CES demand has been shown by Helpman et al. (2004) and is illustrated in Figure 7. Profits under both regimes are linear in an increasing power function of productivity; profits under FDI are lower than under exporting for the lowest-productivity firms, since FDI incurs a higher fixed cost; however, profits under FDI increase faster with

productivity because FDI incurs lower access costs; and the two profit schedules intersect only once as shown.<sup>21</sup> As the lower set of labels indicates, there is now three-way selection, with the least efficient firms not serving the market as before, firms of intermediate efficiency exporting, and the most efficient firms engaging in FDI.

However, Mrázová and Neary (2019) show that this predicted selection pattern is less robust than that for the choice between exporting or not. To see why, consider the upper set of labels in Figure 7. These categorise productivity levels not in terms of their predicted outcomes but in terms of the choices they offer to firms. Low-productivity firms, with costs higher than  $c_S$  (represented by points to the left of  $c_S^{1-\sigma}$  in the figure), face the same choice as before: FDI is not profitable, so the only decision they face is whether to export or not. Mrázová and Neary (2019) call the outcomes of such a decision a “first-order selection effect”: firms face a choice between one activity, exporting, whose profits vary with productivity, and another, not exporting, whose profits are the same for all firms. This is in contrast to the “second-order selection effect” that arise from the choices of high-productivity firms with costs lower than  $c_S$ . For such firms both exports and FDI are profitable, and their profitability in both modes varies with productivity. Hence, the conventional sorting, where more efficient firms select into FDI, is only guaranteed if the two curves have a single intersection as in Figure 7. With a slight abuse of terminology we will refer to this configuration as the single-crossing property.<sup>22</sup>

When might we expect the single-crossing property to hold? One consideration which suggests that second-order selection effects may be less robust than first-order ones comes from Appendix A. We show there that CES demands are the only case in which variable profits are a power function of marginal cost, and so total profits are affine in a simple

---

<sup>21</sup>To ensure that both exports and FDI are observed we require that the two curves intersect in the positive quadrant, which is equivalent to the “freeness” of trade (the variable trade cost adjusted by the degree of substitutability) being greater than the ratio of fixed costs:  $\tau^{1-\sigma} > f_E/f_F$ .

<sup>22</sup>In the language of monotone comparative statics, the condition for  $\Pi^E$  and  $\Pi^F$  to have only a single intersection is that the function  $\Pi^F(c) - \Pi^E(\tau, c)$  is single crossing from above. For details see Mrázová and Neary (2019). For further background on monotonic comparative statics, see Milgrom and Roberts (1990) and Vives (1990).

transformation of productivity as in Figure 7. Thus, with demands other than CES, we need to establish whether the single-crossing property holds and so whether the second-order selection effects will be as illustrated in Figure 7.

Checking directly whether the single-crossing property holds in any particular application is not easy. However, it is easy to check for an important sufficient condition. Recall that  $\pi$  is continuous in  $c$ , and assume also that the two profit functions  $\Pi^F$  and  $\Pi^E$  have different slopes at any point where they intersect. Given this, the single-crossing property is equivalent to  $\Pi^F$  being steeper than  $\Pi^E$  at any productivity level where they intersect, the configuration shown in Figure 7. This suggests a sufficient condition for second-order selection effects which is much easier to check: if  $\Pi^F$  is steeper than  $\Pi^E$  at *every* level of productivity, then single crossing must hold. This condition is equivalent to  $\pi_c(1, c) < \pi_c(\tau, c)$  at every value of  $c$ , which, provided  $\pi$  is twice differentiable in  $(\tau, c)$ , is equivalent to a restriction on its second derivative:  $\pi_{c\tau}$  is positive, or  $\pi(\tau, c)$  is *supermodular* in  $(\tau, c)$ . A necessary and sufficient condition for  $\pi_{c\tau} > 0$  can be found in turn by differentiating (22) with respect to  $\tau$ :

$$\pi_{c\tau} = -x - \tau \frac{\partial x}{\partial \tau} = -x \left( 1 + \frac{d \log x}{d \log c} \right) \quad (24)$$

Hence  $\pi(\tau, c)$  is supermodular in  $\{\tau, c\}$  if and only if  $-d \log x / d \log c > 1$ ; i.e., if and only if the elasticity of output with respect to marginal cost is greater than one in absolute value. (In what follows we denote this by “EMR” since it is also the elasticity of output with respect to marginal revenue.) To understand this condition, note that supermodularity is a restriction on a second derivative, that is, on a difference in differences: not whether higher trade costs reduce profits, but whether they do so by less for lower-productivity firms. The final term on the right-hand side of (24) shows that they are more likely to do so the more elastic is the volume sold to an increase in costs. Offsetting this is the first term, equal to one: this reflects the fact that higher trade costs reduce profits by less for a firm that is selling less to begin with. Whether or not supermodularity obtains depends on the balance

between these two forces.

An alternative way of writing the condition for supermodularity in (24) allows us to illustrate it in demand-manifold space. It can be expressed in terms of demand parameters by noting that it equals the elasticity of demand times the elasticity of price with respect to marginal cost, already given in (16) above:

$$-\frac{d \log x}{d \log c} = \varepsilon \frac{d \log p}{d \log c} = \frac{\varepsilon - 1}{2 - \rho} \quad (25)$$

Supermodularity therefore requires that the following expression be positive:

$$-\left(1 + \frac{d \log x}{d \log c}\right) = \frac{\varepsilon + \rho - 3}{2 - \rho} \quad (26)$$

Thus, from (24), selection into FDI by large firms is only guaranteed if the EMR is greater than one in absolute value, which from (26) is equivalent to the demand function being sufficiently elastic and/or sufficiently convex that  $\varepsilon$  and  $\rho$  sum to more than three.

Figure 8: Second-Order Selection Effects and Demand

To understand these results, it is helpful first to consider Figure 8, showing the demand and marginal revenue functions for three canonical special cases. Panel (a) shows the CES case, which is an example where the EMR is greater than one. It is easy to check from (25), using the CES values for  $\varepsilon$  and  $\rho$  from (4), that the EMR in this case equals  $\sigma$ , which is greater than one. Hence, if we compare two firms facing the same CES demand function, one with marginal costs 10% lower than the other, the more productive firm will have an

output more than 10% higher than the less productive one. This helps explain the result of Helpman et al. (2004), which exhibits another example of the Matthew Effect: in this case, more efficient firms enjoy higher profits when they engage in FDI.

Panel (c), by contrast, shows the case of linear demands, which is an example where the EMR is less than one for larger firms. Intuitively, for such large firms the additional trade cost they must pay if they export is small, since their production cost is low to begin with, and trade costs are proportional to production costs; moreover it reduces their sales very little, since the marginal revenue curve is not steep. Hence, supermodularity fails for larger firms under linear demands, and it can be shown that the largest ones will indeed exhibit reverse selection effects, choosing to export rather than to engage in FDI.

Finally, Panel (b) shows a knife-edge case with the property that the EMR equals one. As a result, the proximity-concentration trade-off yields the same outcome for all firms irrespective of their productivity: the  $\Pi^X$  and  $\Pi^F$  curves in Figure 7 are parallel. Hence, no firms will find it profitable to engage in FDI since it incurs a higher fixed cost, and so no selection will be observed. Mrázová and Neary (2019) show that this demand function is the inverse translog,  $p(x) = \frac{\beta'}{x}(\log x + \gamma')$ . It is a limiting case of a family of demand functions that exhibit a constant EMR:  $d \log x / d \log c = -\kappa$ . Mrázová et al. (2015) call this the “CEMR” family:<sup>23</sup>

$$p(x) = \frac{\beta}{x} \left( x^{\frac{\kappa-1}{\kappa}} + \gamma \right) \quad \beta(\kappa - 1) > 0 \quad (27)$$

The corresponding CEMR manifold is  $\rho(\varepsilon) = 2 - \frac{1}{\kappa}(\varepsilon - 1)$ , which implies a family of affine curves in  $(\rho, \varepsilon)$ -space, some of which are illustrated for different values of  $\kappa$  in Figure 9. Of these, the inverse translog, where the EMR is unity, corresponds to the boundary between the sub- and supermodular regions in  $(\rho, \varepsilon)$ -space, the curve labelled “SM” in Figure 9.

---

<sup>23</sup> Mrázová and Neary (2019), who first considered these demands in this context, called them the Inverse PIGL (“price-independent generalized linear”) demand family, drawing on Muellbauer (1975). The inverse translog is a limiting case of the CEMR family as  $\kappa \rightarrow 1$ ,  $\beta \rightarrow \infty$  and  $\gamma \rightarrow -1$ . To see this, set  $\beta = \beta' \frac{\kappa}{\kappa-1}$  and  $\gamma = \gamma' \frac{\kappa-1}{\kappa} - 1$  and evaluate the limit when  $\kappa \rightarrow 1$ .

Figure 9: CEMR Demand Manifolds

## 6 Linking Productivity and Sales Distributions

The final substantive topic we want to discuss goes to the heart of firm heterogeneity in models of monopolistic competition. It concerns the relationship between the shape of the underlying distribution assumed for firm productivities, and the shape of the predicted distribution of firm outcomes, whether the level or the rate of growth of output or sales.<sup>24</sup>

There is a relatively small number of results of this kind. First is the canonical result in the field, due to Helpman et al. (2004) and Chaney (2008): in the Melitz (2003) model of heterogeneous firms, if firm productivities follow a Pareto distribution and demands are CES, then firm sales must also follow a Pareto distribution. Second, going beyond the canonical result, Head et al. (2014) retain the assumption that demands are CES, and show that if firm productivities follow a Lognormal distribution instead of a Pareto then firm sales must also follow a Lognormal distribution. This result is important as there is abundant evidence that the distribution of firm sales is approximately Pareto for the “long tail” of large firms, but is more closely approximated by a Lognormal distribution for the whole population of firms, especially smaller ones: see, for example, Bee and Schiavo (2018).<sup>25</sup>

<sup>24</sup>This section draws on Mrázová et al. (2015).

<sup>25</sup>Some authors have explored models of heterogeneous firms with other productivity distributions, including generalizations or combinations of the Lognormal and Pareto such as mixtures of thin- and fat-tailed

Both these results share two features. First, they assume CES demands, and so imply that all firms have the same markups which do not vary over time. Second, they exhibit a property that Mrázová et al. (2015) call “self-reflection”: the distribution predicted for the endogenous random variable takes the same form as, or “reflects,” the distribution assumed for the exogenous random variable. Self-reflection is an attractive property: for example, it is desirable to understand in what circumstances the analytically tractable Pareto distribution can be used for both productivity and sales.<sup>26</sup> Hence, it is desirable to know whether there are demand functions other than the CES that are consistent with this property.

Mrázová et al. (2015) show that the answer to this question is “yes” by deriving conditions for self-reflection of two distributions, where the firm-level variables are linked by a functional relationship. They introduce a class of distributions, the “Generalized Power Function” (GPF) class, that nests many well-known families of distributions, including the Pareto, Lognormal and Fréchet. They then show that, if the distributions of both variables are members of the same family in this class, it then follows that the relationship between the two variables must take a simple power-law form. Moreover, these three conditions are necessary and sufficient for each other in the sense that any two imply the third. In the present context, the variables of interest are productivity and sales revenue, so the requirement for self-reflection is that sales revenue is a power-law function of productivity. Since productivity is the inverse of marginal cost, this is equivalent to a constant elasticity of sales revenue with respect to marginal cost:  $d \log r / d \log c = -\kappa$ . Of course, marginal cost equals marginal revenue in equilibrium, so this condition can also be expressed as a “Constant Revenue Elasticity of Marginal Revenue,” whence the acronym “CREMR”.

The next step is to derive the demand functions that exhibit the CREMR property. It is straightforward to express the elasticity in terms of  $\varepsilon$  and  $\rho$ , using the fact that  $r(x) = xp(x)$

---

Pareto or piecewise Lognormal-Pareto distributions, although these are typically not analytically tractable. See, for example, Luttmer (2007), Eaton et al. (2011), Edmonds et al. (2012), and Nigai (2017).

<sup>26</sup>Mrázová et al. (2015) show that self-reflection is also necessary and sufficient for models of monopolistic competition to exhibit Gibrat’s Law, the classic result due to Gibrat (1931) that a firm’s rate of growth should be independent of its size.

and the expression for the elasticity of output with respect to marginal cost from (25):

$$\frac{d \log r}{d \log c} = \frac{\varepsilon - 1}{\varepsilon} \frac{d \log x}{d \log c} = -\frac{(\varepsilon - 1)^2}{\varepsilon(2 - \rho)} \quad (28)$$

Mrázová et al. (2015) show that the demand functions which ensure that this is constant, which they call CREMR demands, are given by the following:

$$p(x) = \frac{\beta}{x} (x + \gamma)^{\frac{\kappa}{\kappa+1}}, \quad \kappa > 0, \quad x + \gamma(\kappa + 1) > 0, \quad \beta > 0 \quad (29)$$

Once again, this is a generalization of CES demands, and reduces to them when  $\gamma$  is zero. The results of Mrázová et al. (2015) imply that it is the only demand function that is consistent with self-reflection of the productivity and sales distributions in monopolistic competition, when both distributions are members of the same family from the GPF class. Mrázová et al. (2015) show that it also has other desirable properties: in particular, it implies distributions for both sales and markups that are both theoretically plausible and empirically realistic, in that they provide a better fit for these distributions than other widely-used demand functions.

Figure 10: CREMR Demand Manifolds

Finally, we can calculate the CREMR demand manifold, which is given by the following:

$$\rho(\varepsilon) = 2 - \frac{1}{\kappa} \frac{(\varepsilon - 1)^2}{\varepsilon} \quad (30)$$

Figure 10 illustrates some examples of this for different values of  $\kappa$ . Once again, these are very different from the demand manifolds for standard demand functions, as shown in Figure 2.

## 7 Constant Response Demand Functions

	Response	Demand Function $p(x; \beta, \gamma, \kappa)$	Demand Manifold $\rho(\varepsilon; \kappa)$
Bulow-Pfleiderer	$\frac{dp}{dc} = \kappa$	$\beta \left( x^{\frac{1-\kappa}{\kappa}} + \gamma \right)$	$2 - \frac{1}{\kappa}$
CPPT	$\frac{d \log p}{d \log c} = \kappa$	$\frac{\beta}{x} \left( x^{\frac{\kappa-1}{\kappa}} + \gamma \right)^{\frac{\kappa}{\kappa-1}}$	$2 - \frac{1}{\kappa} \frac{\varepsilon-1}{\varepsilon}$
CEMR/Inverse PIGL	$\frac{d \log x}{d \log c} = -\kappa$	$\frac{\beta}{x} \left( x^{\frac{\kappa-1}{\kappa}} + \gamma \right)$	$2 - \frac{1}{\kappa} (\varepsilon - 1)$
CREMR	$\frac{d \log r}{d \log c} = -\kappa$	$\frac{\beta}{x} (x + \gamma)^{\frac{\kappa}{\kappa+1}}$	$2 - \frac{1}{\kappa} \frac{(\varepsilon-1)^2}{\varepsilon}$

Table 1: Constant-Response Demand Functions

Table 1 summarizes the demand functions that have been discussed in the paper. Each of them is a “constant-response demand function,” which is necessary and sufficient for an exogenous change in marginal cost to induce an equal absolute or relative response in some firm-level variable, whether price, output or sales. Each of them nests CES demands, and reduces to the CES case when the parameter  $\gamma$  is zero.<sup>27</sup> Putting this differently, only CES

<sup>27</sup>This is immediate in three of the four cases. In the CPPT case we have not shown it explicitly, as it is clear from (17) that CES demands imply that  $\frac{d \log p}{d \log c} = 1$ . For all four demand functions, the CES special case imposes restrictions on  $\kappa$ . Setting  $\varepsilon$  and  $\rho$  in the final column of Table 1 equal to their CES values (given in (4)), the implied values of  $\kappa$  with CES demands are:  $\sigma/(\sigma - 1)$  for Bulow-Pfleiderer, one for CPPT,  $\sigma$  for CEMR, and  $\sigma - 1$  for CREMR, where  $\sigma$  is the CES elasticity of substitution and demand.

demands imply constant responses to costs of more than one of these variables, and each of the four demand functions in Table 1 allows for variable markups if and only if  $\gamma$  is non-zero.

The explicit expressions for the different demand functions given in the third column of the table are suggestive. Yet, even though they are written in such a way as to make them as comparable as possible, their behavior relative to each other is not immediately obvious. It is easier to compare their properties using their manifolds, as shown in the fourth column, and as illustrated in Figures 6, 9, and 10. While each demand function depends on three parameters, each of the manifolds depends only on  $\kappa$ , the parameter that measures the response of the variable in question to the change in marginal cost. Thus, as we have seen in previous sections, for a given value of  $\kappa$ , each manifold is a locus of values of  $\varepsilon$  and  $\rho$  which ensure that the relevant response to an increase in marginal cost is constant and equal to  $\kappa$ .

Except for the Bulow-Pfleiderer case, the other three demand functions in Table 1 have manifolds that are mostly quite different from those of the better-known and more widely-used demand functions shown in Figure 2. If we concentrate on the subconvex case, we can see that these demand functions allow for much more concavity than most widely-used demands. This is especially true for firms that are small and relatively unresponsive to shocks (i.e., for high values of  $\varepsilon$  and low values of  $\kappa$ ). Mrázová et al. (2015) point out that this ability to allow small firms to face very concave demand may be why CREMR demands give a better fit to both sales and markups than other demand systems. By contrast, for larger firms (i.e., for lower values of  $\varepsilon$ ), Bulow-Pfleiderer demands have constant convexity by construction, whereas the others become steadily more convex: CPPT and CEMR asymptote to Cobb-Douglas, and CREMR to a general CES with elasticity of demand  $\sigma$  equal to  $\kappa + 1$ .

While the manifolds in Table 1 are invariant with respect to the other two demand parameters  $\beta$  and  $\gamma$ , this does not imply that these have no role. Consider first the non-CES parameter  $\gamma$ : its sign is a key determinant of whether a given demand function is sub- or superconvex. More specifically, if, for a given value of  $\kappa$ , a demand function can be either sub- or superconvex, then it is superconvex if and only if  $\gamma$  is positive. Table 3 in

Appendix C illustrates the possible configurations in detail. As for the parameter  $\beta$ , its role in these demand functions is similar to the one it plays in the CES itself: it affects only the level of demand, and is taken as given by firms, but is determined endogenously in general equilibrium. We saw in Section 3 how this gives rise to competition effects. In general, any exogenous shock to an industry equilibrium will have both a direct effect on individual firms and an indirect competition effect working through the free entry condition and the demand function. As we saw in Section 3, the competition effect operates in a particularly simple way when demand is generated by additively separable preferences, since it affects only  $\beta$ , which is inversely proportional to the marginal utility of income. Finally, a further role played by the  $\beta$  parameter arises if we want to move from demands to preferences. All of the demand functions in Table 1 can be integrated to get the corresponding preference system, which allows us to solve for the endogenous value of  $\beta$ . This is relatively straightforward when cross-price effects take a simple form, as in the case of additive separability or Kimball preferences. (Mrázová et al. (2015) discuss this further for CREMR demands.) Hence, these demand functions can be used in explicit calculations of the general-equilibrium welfare effects of policy and other shocks.

Finally, in both theoretical and empirical applications it may be convenient to work with demand functions that nest some or all of the families in Table 1. By introducing just one extra parameter we can write a generalized constant-response demand function that nests the CPPT, CEMR and CREMR cases.<sup>28</sup> This takes the following form:

$$p(x) = \frac{\beta}{x} (x^\alpha + \gamma)^\theta \quad (31)$$

It is obvious by inspection that this nests the CPPT, CEMR and CREMR demand functions. Moreover, we can check that it implies a constant proportional response to a change in

---

<sup>28</sup>We can introduce yet one further parameter to write a generalized demand function that nests all four cases in Table 1. However, whereas the constant response implied by Bulow-Pfleiderer demands is an absolute one, we focus here on nesting the three demand functions (CPPT, CEMR and CREMR) that imply a constant proportional response to costs of a variable that we can also nest by a general constant response function implied by (31).

marginal cost of a Cobb-Douglas function of quantity and price,  $f(x) = x^\mu p(x)^{1-\mu}$ . Write the constant response as  $-\kappa'$ . It can be written as a function of  $\mu$  and of the elasticity and convexity of demand by making use of the relationship between output and marginal cost from (25):

$$\frac{d \log f(x)}{d \log c} = \frac{d \log f(x)}{d \log x} \frac{d \log x}{d \log c} = - \left( \mu - \frac{1-\mu}{\varepsilon} \right) \frac{\varepsilon - 1}{2 - \rho} = -\kappa' \quad (32)$$

This can be rearranged to get the demand manifold:

$$\bar{\rho}(\varepsilon) = 2 - \frac{\mu\varepsilon - 1 + \mu\varepsilon - 1}{\kappa' \varepsilon} \quad (33)$$

It can be checked that the parameters  $\alpha$  and  $\theta$  in (31) are uniquely related to the parameters  $\kappa'$  and  $\mu$  in (33):

$$\alpha \equiv \frac{\kappa' + 1 - 2\mu}{\kappa'} \quad \text{and} \quad \theta \equiv \frac{\kappa'}{\kappa' + 1 - \mu} \quad (34)$$

The three special cases correspond to values of  $\mu$  equal to zero in the CPPT case (when  $\kappa = -\kappa'$ ), equal to one in the CEMR case (when  $\kappa = \kappa'$ ), and equal to  $\frac{1}{2}$  in the CREMR case (when  $f(x)$  is the square root of revenue rather than revenue itself, so  $\kappa = 2\kappa'$ ). Figure 11

Figure 11: Nesting Constant-Response Demand Functions

illustrates schematically how the different constant-response demand functions relate to each

other: all except Bulow-Pfeiderer demands are nested by (31), and the CES is the only demand function that is nested by all.<sup>29</sup>

## 8 Conclusion

In this paper we have reviewed and extended recent work by ourselves and others on monopolistic competition in benchmark models of international trade.<sup>30</sup> We have concentrated on the implications of such models for a number of important results, including competition effects, pass-through, selection effects, and the size distribution of firms. One unifying principle we have emphasized is that the assumption of CES preferences and demands yields enormous analytical tractability, but also has very restrictive and often counter-factual implications. In a CES world, competition effects take a very simple form: all firms have the same markup, and globalization shocks leave the distribution of profits across firms unchanged; pass-through from costs to prices is always exactly 100%; larger firms always select into activities with lower access costs; and the distributions of productivity and sales typically exhibit the same form. A second unifying principle that we have highlighted is the class of constant-response demand functions that provide a parsimonious suite of alternatives to the CES case. Each of these functions adds a single parameter to the CES, so avoiding the counter-factual prediction of constant markups, while preserving one or other of its key properties. Given the dominance of monopolistic competition in trade, these demand functions provide a route to more realistic modelling and empirical work. Moreover, the generalized constant-response demand function that we introduced in Section 7 will hopefully prove helpful in giving a unified perspective on the different individual constant-response functions and in understanding how they relate to each other.

---

<sup>29</sup>Matsuyama and Ushchev (2017) illustrate in a similar way links between non-parametric homothetic departures from CES.

<sup>30</sup>As already mentioned, we have not discussed trade under oligopoly, which provides an alternative explanation for the evidence of variable markups cited in Section 2.3. (See, for example, Neary (2003, 2016) and Atkeson and Burstein (2008).) Nor have we discussed the extensive recent literature in trade that uses calibration methods to quantify the effects of exogenous shocks, often in CES-based frameworks. (See Costinot and Rodríguez-Clare (2014) for an overview.)

The fact that the monopolistically competitive paradigm has become the dominant one in international trade may seem surprising from an IO perspective. However, there are good reasons for this. The availability of large data sets on exporting firms, and the desire to take account of general-equilibrium feedbacks between goods and factor markets, make a “one-size-fits-all” approach to the choice of market structure very convenient. This is despite the fact that it is sure to miss much of the supply-side specificity on which IO economists tend to focus, including industry-specific features such as limit pricing in some industries but not in others, differences in fixed costs, the role of learning-by-doing, etc. Moreover, as we have shown, relaxing the assumption of CES preferences in monopolistic competition makes its view of firms more realistic and its predictions more flexible.

Of course, while leaving the comfort zone of CES goes part of the way to a more realistic view of imperfectly competitive markets, it raises new problems. To paraphrase Tolstoy (1878), CES demand functions are all alike, every non-CES demand function is non-CES in its own way.<sup>31</sup> The CES benchmark is sure to retain a central place in this field, both because of its tractability and also because it alone exhibits all the constant-response properties that we have discussed.

In conclusion, we have already noted some ironies in the selective way in which international trade has borrowed from industrial organization in how it models firms in open economies. In particular, Dixit and Stiglitz proposed using additively separable preferences as a way of modelling product differentiation, and viewed CES preferences as just a special illustrative case; whereas it is the latter that has become the workhorse model for exploring a huge range of issues in trade. There is a further irony. The substantive issue Dixit and Stiglitz addressed was the efficiency of the market equilibrium, and in particular whether an unregulated monopolistically competitive market would lead to too many or too few varieties, and to firms that are too large or too small relative to the social optimum. This issue has not been addressed much in trade, but in recent years there has been a revival of

---

<sup>31</sup>From the opening sentence of *Anna Karenina*: “Happy families are all alike; every unhappy family is unhappy in its own way.”

interest in it: see for example Feenstra and Kee (2008) and Dhingra and Morrow (2019). In ongoing work with Mathieu Parenti (see Mrázová et al. (2015)) we show how the tools from Section 6 above can be used to throw light on this issue.

# Appendices

## A Constant Response of Profits Demand Functions

We would like to characterize the demand functions with the property that operating profits have a constant proportional response to marginal cost:  $\frac{d \log \pi}{d \log c} = \kappa$ . We know that this holds in the CES case, where  $\pi = Bc^{1-\sigma}$ .<sup>32</sup> To find the necessary condition for this property, note that, since  $\pi = (p - c)x$ , we have in general:

$$d \log \pi = d \log (p - c) + d \log x \quad (35)$$

Equation (25) gives the proportional response of output to changes in marginal cost,  $d \log x / d \log c$ . The next step is to consider  $d \log (p - c)$ . Consider first  $d(p - c)$ . From the firm's first-order condition this equals  $d(-xp') = -p'dx - xp''dx = -(p' + xp'')dx$ . Hence:

$$d \log (p - c) = \frac{d(-xp')}{-xp'} = \frac{(p' + xp'')dx}{xp'} = \frac{p' + xp''}{p'} d \log x = (1 - \rho) d \log x \quad (36)$$

Collecting terms gives, from (25) and (35):

$$\frac{d \log \pi}{d \log c} = \frac{d \log (p - c)}{d \log c} + \frac{d \log x}{d \log c} = (2 - \rho) \frac{d \log x}{d \log c} = -(\varepsilon - 1) \quad (37)$$

---

<sup>32</sup>Here  $B$  is exogenous from the firm's perspective, but it depends on the price index and on aggregate income, and so is endogenous in general equilibrium. See, for example, Melitz (2003), equation (4).

Clearly the CES case is the only one that yields a constant value of this. Hence CES demands are necessary and sufficient for a constant proportional response of operating profits to marginal cost. This in turn implies that there is no other demand function which guarantees that profits are affine in a power-law transformation of costs, so we must seek other conditions, such as supermodularity of the profit function in production and trade costs, to be sure that second-order selection effects follow the same pattern as they do in the CES case.

## B Manifolds for Some Common Demand Functions

	Demand Function	Demand Manifold
CARA	$x(p) = \gamma + \delta \log p$	$\rho(\varepsilon) = \frac{1}{\varepsilon}$
Stone-Geary/LES	$p(x) = \frac{\beta}{\gamma x + 1}$	$\rho(\varepsilon) = \frac{2}{\varepsilon}$
Translog/AI	$x(p) = \frac{1}{p} (\gamma + \delta \log p)$	$\rho(\varepsilon) = \frac{3\varepsilon - 1}{\varepsilon^2}$

Table 2: Some Common Demand Functions and Their Manifolds

Table 2 gives some common demand functions and their manifolds, as illustrated in Figure 2. Further details are given in Mrázová and Neary (2017). As elsewhere in the paper, the demand functions are written from the perspective of an individual firm in monopolistic competition. They also depend on aggregate expenditure and on indices of the prices of all goods, including the good in question; these are taken as given by the firm, since it is of measure zero, and are subsumed into the demand parameters. (See Dixit and Stiglitz (1993) for further discussion.) All three manifolds are invariant with respect to these other variables. To take a specific example, Stone-Geary demands are more familiar when written as:  $x(i) = \alpha(i) + (p(i))^{-1} (I - \int_{i' \in \Omega} p(i') \alpha(i') di')$ , which, when  $\gamma = (-\alpha(i))^{-1}$  and  $\beta =$

$\gamma (I - \int p(i')\alpha(i')di')$ , is equivalent to the expression in Table 2. The latter expression is the special case of the CPPT demands from (18) when  $\kappa = 1/2$ .

## C The Role of $\gamma$ in Determining Superconvexity

		$\gamma < 0$		$\gamma > 0$	
$\kappa < 1$	BP:	n/a	BP:	Subconvex	
	CPPT:	n/a	CPPT:	Subconvex	
	CEMR:	n/a	CEMR:	Subconvex	
	CREMR:	Subconvex	CREMR:	Superconvex	
$\kappa > 1$	BP:	Subconvex	BP:	Superconvex	
	CPPT:	n/a	CPPT:	Superconvex	
	CEMR:	Subconvex	CEMR:	Superconvex	
	CREMR:	Subconvex	CREMR:	Superconvex	

Table 3: Possible Configurations of Sub- and Superconvexity

Table 3 illustrates schematically the conditions under which each of the non-CES constant-response demand functions is either sub- or superconvex, depending on the values of the  $\gamma$  and  $\kappa$  parameters. In four of the eight cases, the demand functions can only be either sub- or superconvex, irrespective of the sign of  $\gamma$ . The remaining cases are represented in Figures 6, 9, and 10 by manifolds with two branches, one in the subconvex region and the other in the superconvex one. It is in these cases that the sign of  $\gamma$  is crucial, with a positive value corresponding to the superconvex branch.
